FOREWORD

The research on this program was performed by personnel of the Electromagnetic Effectiveness Division of the Electronics and Computer Systems Laboratory of the Engineering Experiment Station at Georgia Institute of Technology, Atlanta, Georgia 30332. Dr. C. E. Ryan, Jr. served as the Project Director. This program is sponsored by the Army Research Office, P.O. Box 12211, Research Triangle Park, North Carolina 27709, and is designated by Georgia Tech as Project A-2610. This Final Technical Report covers the period form March 15, 1980 through May 14, 1981. The report summarizes the key results and is provided for the purpose of disseminating technical information to interested parties.

Respectfully submitted,

Charles E. Ryanh

SECTION I INTRODUCTION

The characterization of the radiation properties of antennas at outof-band frequencies has become increasingly important as the density of cosited antennas increases. For example, a high power system operating in X-band can cause interference to an S-band system by mainbeam-to-mainbeam, mainbeam-to-sidelobe, or sidelobe-to-sidelobe coupling. The typical waveguide feed and components of the S-band system are capable of supporting the higher frequency X-band radiation in the form of higherorder modes which propagate in the transmission waveguide of the feed system. It has been shown in the past that these modes are very sensitive to the particular feed system and to the component mix in the feed system. The purpose of this research project was to construct a computer algorithm which could be used to determine the statistical average patterns for an antenna operating at an out-of-band frequency. The particular antenna which was chosen for the model is a prime focus fed paraboloidal reflector which utilizes a conventional horn feed terminated in a coax-to-waveguide adapter. However, we should note that the program which was developed is quite general and if the statistics of the particular feed device are known or can be hypothesized, these particular statistics can be utilized in the model. Briefly, the model determines which higher-order modes can exist within the feed waveguide, and selects weighting coefficients both in amplitude and phase for these modes on the basis of a random draw from a specified statistical distribution. The particular mode set which has been drawn is utilized to determine the feed pattern for each mode, the resulting aperture distribution, and thus, via a Fourier transformation, the far-field pattern of the antenna for this specific mode. The far-field patterns corresponding to the individual modes are then superimposed to determine the pattern for that particular draw of weighting coefficients. These draws are repeated in a Monte Carlo technique to determine a complete statistical average far-field pattern. A feature of the present computer algorithm is that the analyst may choose to select sets of modes which correspond to the characteristics of known feed devices. For instance, since the coax-to-waveguide adapter is normally center fed, it is a generator of the odd order TE modes. That is, the TE10, TE30, TE50, etc.

Thus, to model this particular feed component, one may choose to eliminate the even ordered TE modes TE20, TE40, TE60, etc. However, we should note that even for the case of a coax-to-waveguide adapter, measured antenna patterns seem to indicate that some even TE modes may exist [1]. This can be due to minor variations in the manufacturing tolerances or to other discontinuities in the feed structure. It should be noted that extensive measured data is presently being obtained under another research contract on the out-of-band characteristics of a prime focus fed paraboloidal reflector [2]. These data will subsequently be statistically analyzed to obtain engineering data on the type of mode distributions which should be expected for a practical antenna. The present computer model is sufficiently adaptable so that when future information regarding the statistical mode distribution is available, it can be readily incorporated in the model. The following sections of this report will describe the methodology used to construct the model, the computer model architecture and subroutines which are employed for the computations, and present results of calculated statistical average and individual far-field radiation patterns. The present model performs a complete vector calculation of the far-field pattern but does not include effects such as edge diffraction from the paraboloidal reflector rim, blockage by the feed horn structure or diffraction by the feed horn. These features can be incorporated in the model at some future date.

SECTION II

MONTE CARLO ANALYSIS OF THE OUT-OF-BAND PARABOLOIDAL REFLECTOR ANTENNA

A. Introduction

The types of microwave antennas and their range of applications are constantly increasing. It is natural that problems which were previously neglected would become important. The interference or coupling between devices operating in different frequency bands is such a problem and is particularly important when many antennas must be operated on relatively small platforms. The analysis presented here addresses a limited portion of this problem, namely the out-of-band radiation characteristics of the class of paraboloidal reflector antennas.

The radiation pattern of such an antenna can be calculated by conventional deterministic analysis and a knowledge of all system variables. The feed network, however, can support multi-mode energy propagation and a calculation of the relative phases and amplitudes of the different modes requires a detailed knowledge of the feed network. This is generally a very difficult boundary value problem. Further, the coefficients of the modes will be quite sensitive to minor electrical and mechanical variations in the feed network so that nominally identical systems can produce distinctly different out-of-band patterns. This characteristic out-of-band pattern sensitivity is evident from experimental and theoretical studies [1,3,4,5]. In order to account for these random effects, the out-of-band mode excitation coefficients may be considered to be random variables. Treatment of these modal coefficients as random variables serves a double purpose. First, it allows the analysis to proceed independent of the feed structure (which may vary between otherwise identical antennas). Second, it leads to a statistical result that can account for variations in fabrication and excitation of the nominal antenna. In a similar manner, the out-of-band frequency may also be treated as a random variable. In this case the interference effects due to sources throughout a frequency band will not require separate analysis and also, interference from pulsed, and hence wide-band, sources can be assessed.

It does not seem appropriate to treat the physical parameters of the feed horn or reflector as random variables. These parameters impact in-

band performance directly and so are controlled during fabrication. At the in-band frequency, higher-order modes are attenuated in the feed system and hence are not of interest to the design engineer. Therefore, random variation of the higher-order modal coefficients at out-of-band frequencies should be expected and should have a greater effect than typical variations of focal length, feed horn dimensions, etc. These geometrical variations will affect the reflector optics but will have a relatively minor effect on the aperture distribution and a correspondingly minor effect on the antenna pattern. However, the higher order mode coefficients directly affect the aperture distribution and hence have a major impact on the characteristics of the far-field pattern.

The following paragraphs describe the Monte Carlo analysis of prime focus fed paraboloidal reflector antennas wherein the operating frequency and modal coefficients are treated as random variables. Later it will be seen that the restriction to feeds at the focal point can be relaxed. The analysis determines Monte Carlo average fields and power patterns both in the near-field and in the far-field. The statistical planar near-fields can be used in the calculation of coupling between closely situated antennas. Since near-field measurements of ensembles of antennas operating at out-of-band frequencies have been performed [6], it is useful and convenient to determine how accurately the statistical far-field can be derived from the simple statistical near-field data. (Note that the ensemble of near-field measurements might involve only one antenna operated at different frequencies.) It should be apparent before any analysis, that the results are dependent on the distributions of modal coefficients and frequencies, and hence that the specialization of the model to a specific problem is equivalent to a specification of these statistical distribution functions.

Statistical analysis is generally accomplished by summations over the deterministic quantities in the problem. Thus, this analysis begins with the deterministic calculation of the fields of a paraboloidal reflector antenna. The calculation is a vector calculation as is essential due to the large cross polarized components of the higher-order modal fields.

B. Deterministic Calculation

The deterministic calculation is made using the conventional ray optics technique. The origin is chosen at the focus with the z-axis along

the axis of symmetry and toward the paraboloid as shown in Figure (1).

Paraboloids of revolution form a one-parameter family of surfaces. All of them are described in this coordinate system by

$$z = \frac{x^2 + y^2}{4f} + f$$
 (1)

where f is the focal length of the paraboloid.

The field in the aperture plane of the feed horn is a summation of the TE_{mn} and TM_{mn} modal fields that exist in the waveguide but with a phase taper that arises from the flare of the feed horn. The transverse fields are (unnormalized)

$$E_{\mathbf{x}}(\mathbf{x}',\mathbf{y}') = \frac{n\pi}{b_{\mathbf{F}}} \cos\left(\frac{m\pi\mathbf{x}'}{a_{\mathbf{F}}}\right) \sin\left(\frac{n\pi\mathbf{y}'}{b_{\mathbf{F}}}\right) e^{i\phi(\mathbf{x}',\mathbf{y}')}$$

$$E_{\mathbf{y}}(\mathbf{x}',\mathbf{y}') = \frac{m\pi}{a_{\mathbf{F}}} \sin\left(\frac{m\pi\mathbf{x}'}{a_{\mathbf{F}}}\right) \cos\left(\frac{n\pi\mathbf{y}'}{b_{\mathbf{F}}}\right) e^{i\phi(\mathbf{x}',\mathbf{y}')} \tag{2}$$

for the TEmn modes and

$$E_{\mathbf{X}}(\mathbf{x',y'}) = \frac{m\pi}{a_{\mathbf{F}}} \cos \left(\frac{m\pi\mathbf{x'}}{a_{\mathbf{F}}}\right) \sin \left(\frac{n\pi\mathbf{y'}}{b_{\mathbf{F}}}\right) e^{i\phi(\mathbf{x',y'})}$$

$$E_{\mathbf{y}}(\mathbf{x',y'}) = \frac{n\pi}{b_{\mathbf{F}}} \sin \left(\frac{m\pi\mathbf{x'}}{a_{\mathbf{F}}}\right) \cos \left(\frac{n\pi\mathbf{y'}}{b_{\mathbf{F}}}\right) e^{i\phi(\mathbf{x',y'})} \tag{3}$$

for the TM_{mn} modes where a_F and b_F are the x and y dimensions of the feed horn aperture and

$$x' = x + a_F/2$$

 $y' = y + b_F/2$ (4)

are distances measured from the corner of the feed horn, and ϕ (x',y') is the phase taper function. The field terms are expressed most simply in terms of distances from the edges of the feed horn since they arise from the imposition of boundary conditions at these edges. The phase taper function, which is not dependent on the mode, is more readily expressed as

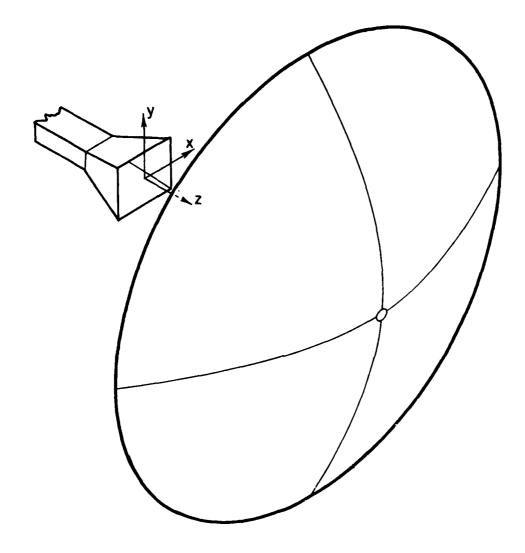

Figure 1. The origin of the coordinate system and the center of the feed horn are at the focus of the paraboloid. The z-axis is directed toward the paraboloidal surface along the axis of symmetry. The x-axis is parallel to the long side of the waveguide.

a function of x and y, the coordinates of Figure 1, originating at the center of the feed horn. The phase taper is

$$\phi (\mathbf{x},\mathbf{y}) = \frac{\pi f}{c} \mathbf{x}^2/h \tag{5}$$

for a horn with an H-plane flare and

$$\phi (x,y) = \frac{\pi f}{c} y^2/h \tag{6}$$

for a horn with an E-plane flare where h is the length of the horn. Note that the long side of the waveguide is parallel to the x-axis so that an H-plane flare is a variation of the x dimension of the horn. The phase taper terms are independent of mode because they represent only the differences in electrical path lengths to the face of the horn.

The far-field of the feed horn is proportional to the Fourier Transform of the feed horn aperture field. It is assumed that the reflector is in the far-field of the feed horn and that ray optics describes the propagation of energy from the feed horn, via the reflection to the aperture plane. Also blockage due to the feed horn is neglected. These approximations and the use of the discrete Fourier Transform are the basis of the numerical code.

The expressions for the far-fields of the feed horn are given as [7]

$$E_{\theta} = (A_{\mathbf{x}}(k_{\mathbf{x}}, k_{\mathbf{y}}) \cos \phi + A_{\mathbf{y}}(k_{\mathbf{x}}, k_{\mathbf{y}}) \sin \phi)/r, \qquad (7)$$

$$E_{\phi} = (-A_{\mathbf{x}}(k_{\mathbf{x}}, k_{\mathbf{y}}) \sin \phi + A_{\mathbf{y}}(k_{\mathbf{x}}, k_{\mathbf{y}}) \cos \phi) \cos \phi/r,$$

where
$$A_{x}(k_{x},k_{y}) = \iint dxdy \ E_{x}(x,y)e^{-j(k_{x}X + k_{y}Y)}$$
and
$$A_{y}(k_{x},k_{y}) = \iint dxdy \ E_{y}(x,y)e^{-j(k_{x}X + k_{y}Y)}$$

are the Fourier Transforms of the feed horn fields E_X and E_y , and θ and ϕ are the normal elevation and azimuth angles defined for the coordinates of Figure 1. The radius r is the distance to the far-field point from the center of the feed horn aperture. The relation of the wave-numbers k, k to the far field angles is given by

$$kx = k_0 \sin \cos x$$
 $ky = k_0 \sin \sin y$
(8)

where $k_0 = 2\pi/\lambda$.

These components of the field are incident on the conducting parabaloidal surface and so are completely reflected along lines parallel to the z-axis (this follows from the definition of the paraboloid). The components of the reflected ray are still perpendicular to the direction of propagation after reflection and so lie in the xy-plane. It is convenient to define an aperture plane for the reflector antenna system parallel to the xy-plane and for definiteness, coinciding with the rim of the paraboloid. The reflected \mathbf{E}_{θ} and \mathbf{E}_{ϕ} components lie in the aperture plane, are perpendicular to each other, and are rotated to an angle ϕ relative to the xy axes. Therefore the x and y components of the aperture field $\mathbf{E}_{\mathbf{X}}^{A}$ and $\mathbf{E}_{\mathbf{Y}}^{A}$, are given by

$$E_{\mathbf{x}}^{\mathbf{A}} = C(E_{\theta} \quad \cos\phi \quad -E_{\phi} \quad \sin\phi)$$

$$E_{\mathbf{y}}^{\mathbf{A}} = C(E_{\theta} \quad \sin\phi \quad +E_{\phi} \quad \cos\phi).$$
(9)

The proportionality constant C must account for space loss. There are no new phase difference terms because all ray paths from the focus to the paraboloid to the aperture plane are of equal length. The most direct determination of the space loss factor is by conservation of energy. As illustrated in Figure 2, rays from the focus diverge till they strike the reflector and then propagate parallel to one another to the aperture plane. Consider the bundle of rays that passes through an element S_F of the spherical surface a distance r from the focal point. These rays are reflected and pass through an area element S_A of the aperture plane. It is apparent physically that the energy of the ray bundle crossing S_F and S_A must be the same. This is clear formally by considering the closed surface consisting of S_F and S_A and the surfaces formed the rays that strike the edges of S_F and S_A and that part of the reflector S_P that the ray bundle intersects. This surface is denoted by S_F . Conservation of energy is imposed as

$$\int_{S} \vec{E} \times \vec{H}^* \cdot \hat{n} dS = 0$$
 (10)

where \hat{n} is the unit outward normal to the surface. The surfaces parallel to the rays make no contribution to the integral. The surface S_p lies within the reflector and, since the reflector is a good conductor, the fields on S_p are zero. Thus Equation (10) reduces to

$$\int_{S_{F}} \vec{E} \times \vec{H} \cdot \hat{n} ds + \int_{S_{A}} \vec{E} \times \vec{H} \cdot \hat{n} ds \approx 0.$$
 (11)

For differential area elements and the plane waves of ray optics this becomes

$$-\int_{\phi}^{\phi+\Delta\phi} \int_{\theta}^{\theta+\Delta\theta} E^{2} r^{2} \sin\theta d\theta d\phi + \int_{\rho}^{\rho+\Delta\rho} \int_{\phi}^{\phi+\Delta\phi} E^{2} \rho d\rho d\phi = 0$$
 (12)

with notation as defined in Figure 2. The fact that the ray and the normal to the surface have opposite orientations on S_F and S_a is responsible for the minus sign in Equation (12). For differential area elements this becomes

$$\begin{array}{cccc}
2 & 2 \\
\mathbf{E_F} & \mathbf{S_F} &= \mathbf{E_A} & \mathbf{S_A},
\end{array} \tag{13}$$

or

$$E_F^2 r^2 \Delta \phi \sin \theta \Delta \theta = E_A^2 \Delta \phi \rho \Delta \rho,$$
 (14)

from which one determines that

$$E_{\mathbf{F}}^{2}/E_{\mathbf{A}}^{2} = \frac{\rho}{r \sin \theta} \frac{d\rho}{d\theta}$$
 (15)

This is evaluated by rewriting Equation (1) for the paraboloidal surface as

$$\rho = r_p \sin\theta = 2f \sin\theta/(1 + \cos\theta)$$
 (16)

where

$$\rho = x^2 + y^2$$

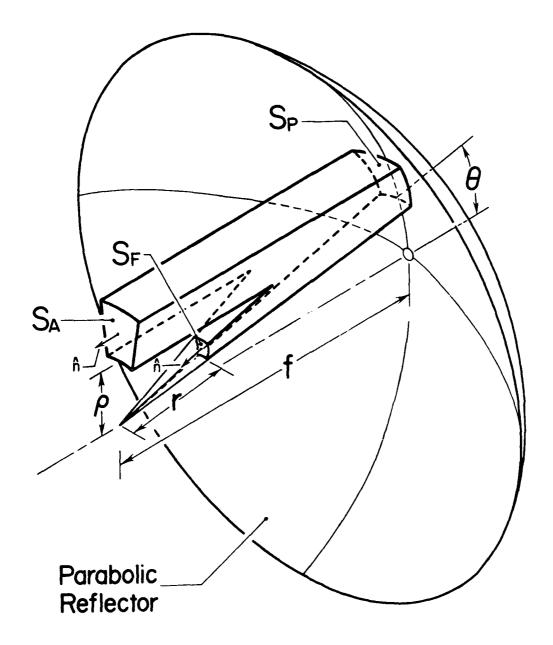

Figure 2. A ray bundle spreading from the focal point and subtending angles $\Delta \phi$ and $\Delta \theta$ of the sphere of radius r about the focal point is depicted. This ray bundle is incident on an area S of the paraboloid and is reflected through an area S_A of the aperture plane of extent $\Delta \phi$, $\Delta \rho$.

and r_p is the distance from the focal point to a point of the paraboloidal surface at an elevation angle θ . The result valid for each component of Equation (9) is

$$E_{A} = \frac{r}{r_{p}} E_{F}$$
 (17)

or $C = r/r_p$ and the r cancels the r in the feed horn far-field components of Equation (7). The x and y components of the aperture field can now be calculated via equations (7), (9), and (17). The field at a point x,y of the aperture plane is related to the Plane Wave Spectrum $\overline{A}(k_x,k_y)$ of the feed horn where k_x , k_y are given in terms of far-field angles about the focal point by Equation (8). With some algebra, it follows from Equation (16) that

$$k_x = 4k_0 f x/(x + y + 4 f^2)$$
 (18)

$$k_y = 4k_0 f y/(x + y + 4 f^2).$$

The calculation of the deterministic aperture field from the field in the feed horn aperture is now complete. The numerical evaluation of this field as implemented in the code PARAB requires the following observations. First note that any field in the feed horn aperture can be written as a sum of modal fields with specified modal coefficients. This principle of superposition follows from the linearity of Maxwell's Equations. Similarly, the far-field of the feed horn is proportional to the Fourier Transform (FT) of the feed horn aperture field and, by linearity of the FT, can be written as the sum of the FT of the modal fields times the modal coefficients. The mapping that represents the reflector is also linear and thus the fields in the reflector aperture and the antenna far-field are a sum over modal fields. One can therefore calculate the far-field pattern for each mode independently. The practical importance of treating the modal fields independently is that this allows the separability of the feed horn fields to be used.

Note also that the far-field pattern of the antenna is to be obtained as the FFT (Fast Fourier Transform) of the aperture field. The FFT algorithm assumes a regular rectangular grid of data points $n\Delta$ x, $m\Delta$ y. For $m\epsilon$ {-Ny/2 - 1, ... Ny/2} and n ϵ {-Nx/2 - 1, ... Ny/2} where Nx and

 N_y are the dimensions of the data array. Equation (18) demonstrates that this regular array of points x,y does not correspond to regularly spaced points k_x , k_y . Values of the spectrum of the feed horn must be determined for this non-uniform array of points. These points could be calculated by a two-dimensional polynomial interpolation formula from data points on a uniform rectangular grid obtained by FFT of the feed horn fields. A more accurate method is direct calculation of the Fourier Transform. Such a direct calculation normally requires calculation of a two-dimensional integral for each point of the array and so is prohibitive. In this case, the modal fields are, by Equations (2) and (3), separable functions of x and y so that $A(k_x, k_y)$ for arbitrary k_x and k_y can be calculated by two one-dimensional integrals.

The approximations contained in the deterministic calculation are summarized as follows. The reflector is treated as being in the far-field of the feed horn. It is also assumed that the reflector is circular (that its rim is a circle) and that blockage effects due to the feed system are negligible; other shapes as well as geometrical blocking could readily be implemented (with an increase in the number of input parameters required). Ray optics without diffraction effects is used. The numerical evaluation is based on discrete Fourier Transforms without interpolation. The principal part of the deterministic calculation is implemented in Subroutine REFLEC.

C. Statistical Analysis

As described previously, the statistical problem consists of the treatment of the modal coefficients and the operating frequency as random variables in the calculation of the fields and power of the antenna. The treatment that is implemented is a Monte Carlo calculation wherein sampled values of an assumed distribution of the random variable are used in a deterministic calculation to determine statistical values of the field and its moments. Such a calculation evidently reproduces the results obtained by measurement of an ensemble of antennas if (1) the assumed and actual distribution of the random variables are the same, (2) the deterministic calculation is accurate, and (3) the size of the statistical sample is sufficiently large.

The size of sample required is determined by the precision with which the various statistical moments are to be calculated. In practice, the size of the sample is varied and the effect on the various computed moments of the field are noted. The limitations of the deterministic calculation have already been discussed. The determination of the distribution functions for the frequency and modal coefficients is a separate problem requiring a complete specification of the feed system and sources of higher-order mode generation, including the modal distribution functions. Such specifications are not currently available, although a measurement program [2] is being undertaken to determine the statistics for the case of a coax-to-waveguide fed paraboloidal antenna. Thus the specific calculations to be described in this report are geared to determining the qualitative effects of varying the distribution functions.

A realizable aperture field for the out-of-band antenna can be written as

$$\overline{E}_{A}(x,y,f) = \sum_{m,n,k} C(m,n,k) \overline{E}_{A,m,n,k} (x,y;f)$$
 (19)

where the summation is over all allowable propagating waveguide modes TE_{mn} and TM_{mn} . The value k=1 is associated with TE modes and k=2 with TM modes. The deterministic modal fields in the aperture plane $\overline{E}_{A,m,n,k}$ are as described in the previous section. Their dependence on frequency is through the phase tapers of Equation (5) and (6) and through the k_x and k_y values at which the feed horn spectrum is to be calculated as given by Equation (18), specifically the k_0 factor. The specification of a set of modal coefficients is then sufficient to determine the aperture field $\overline{E}_A(x,y;f)$.

It is clear that the deterministic sperture field can be calculated for any frequency and any set of modal coefficients. Similarly, the deterministic far-field or spectrum can be calculated. Specifically, the spectrum is given by:

$$\overline{A}(k_{x},k_{y};f) = F.T. [\vec{E}_{A}(x,y;f)]$$

$$= \sum_{m,n,k} C(m,n,k) F.T. [\vec{E}_{A,m,n,k}(x,y;f)]$$

$$= \sum_{m,n,k} C(m,n,k) \vec{A}_{m,n,k} (k_{x},k_{y};f) (20)$$

where linearity of the Fourier Transform has been used and spectra $\overline{A}_{m,n,k}$ of the aperture modal fields have been defined. The near-field or aperture power is proportional to

$$P_{\mathbf{n}.f.}^{\mathbf{X}} = |\mathbf{E}_{\mathbf{A}\mathbf{x}}|^{2}$$

$$P_{\mathbf{f}.f}^{\mathbf{y}} = |\mathbf{E}_{\mathbf{A}\mathbf{y}}|^{2}$$
(21)

The spectral power pattern, proportional to the far-field pattern of the antenna, is defined by

$$P_{\mathbf{f} \cdot \mathbf{f}}^{\mathbf{X}} = |\mathbf{A}_{\mathbf{X}}|^{2}$$

$$P_{\mathbf{f} \cdot \mathbf{f}}^{\mathbf{Y}} = |\mathbf{A}_{\mathbf{Y}}|^{2}$$
(22)

Ensemble averages of these quantities can now be written for arbitrary ensembles of frequencies and coefficient sets. These averages are the statistical quantities that will be calculated. Higher moments of the field will be important in future calculations.

The average of the near-field over an ensemble of coefficient sets is given by

$$\langle E_A \rangle_C = \frac{1}{N_C} \sum_i \overline{E}_A i$$
 (23)

where N_C is the number of coefficient sets in the ensemble and \overline{E}_A is the determinstic aperture or near field that occurs for the set of coefficients $C^i(m,n,k)$. Writing the average in terms of these coefficients as in Equation (19):

$$\langle E_{A} \rangle_{C} = \frac{1}{N_{C}} \sum_{i=m,n,k} C^{i}(m,n,k) \overline{E}_{Am,n,k}(x,y;f)$$

$$= \sum_{m,n,k} \langle C(m,n,k) \rangle_{C} = \overline{E}_{Am,n,k}(k,y;f)$$
 (24)

where

$$(C(m,n,k))_{c} = \frac{1}{N_{c}} \sum_{i} C^{i}(m,n,k).$$

This has the form of Equation (19) and demonstrates that the statistical

coefficient average of the near-field is identically the deterministic near-field that occurs when each mode is present with its average coefficient. The situation is the same for the average of the far-field over an ensemble of coefficient sets as can be seen by replacing EA by A in Equations (23) and (24) and using Equation (20). The situation is not as simple for averages over frequencies or for averages of the near-field or the spectral powers.

Writing the ensemble average over frequencies of the near-field

$$< \overline{E}_{A}>_{f} = \frac{1}{N_{f}} \sum_{i} \sum_{m,n,k} C^{i}(m,n,k) \overline{E}_{A,m,n,k}(x,y;f^{i})$$
 (25)

where N_f is the number of frequencies in the ensemble, it is apparent that the sum cannot be rearranged as in Equation (24) because of the dependence of the modal aperture fields on the frequency. Neither the frequency average of the near-field nor of the spectrum is equivalent to a similar deterministic quantity.

In discussing the deterministic calculation, the dependence of the fields on frequency through the direction cosines $k_x = k_x/k_0$ and $k_y = k_y/k_0$ where $k_0 = 2\pi c/f$ has been noted. This requires careful treatment in forming the frequency average and leads to a distinction between the calculations of near-field and spectral frequency averages. Specifically, the near-field average requires that the modal fields of different frequency be calculated on a regular grid of points x,y in the aperture. By Equation (18), this means that the points k_x, k_y at which the feed horn spectrum must be calculated will be different for different frequencies. On the other hand, the calculation of frequency averages of spectral or far-field quantities, requires that the direction cosines $k_{\mathbf{x}}^{A}$ and $k_{\mathbf{y}}^{A}$ with respect to the aperture plane be the same for the different frequencies. This means that the different frequency fields are calculated on aperture grids with different spacings. If, for a nominal center frequency fo, an aperture grid with an xo spacing is used, then an aperture grid with spacing

$$\Delta x_i = \Delta x_0 f_0 / f_i \tag{26}$$

is used for the frequency fi. Again, the points at which the feed horn

spectrum must be evaluated are given by Equation (18) but with points x,y that are frequency dependent.

With the above background, calculation of the near-field or spectral power averages is straightforward. The averages over frequency ensembles and/or ensembles of coefficient sets are given by

$$\langle P_{n,f}^{x} \rangle_{f,c} = \frac{1}{N_{f,c}} \sum_{i} |E_{Ax}|^{2}$$
 $\langle P_{n,f}^{y} \rangle_{f,c} = \frac{1}{N_{f,c}} \sum_{i} |E_{Ay}|^{2}$
(27)

for the near-field power and

$$\langle P_{f,f}^{x} \rangle_{f,c} = \frac{1}{N_{f,c}} \sum_{i} |A_{x}|^{2}$$
 $\langle P_{f,f}^{y} \rangle_{f,c} = \frac{1}{N_{f,c}} \sum_{i} |A_{y}|^{2}$
(28)

for the spectral power. It should be noted that the sums cannot be expanded and rearranged and that the results are not equivalent to deterministic patterns.

D. An Approximate Statistical Far-Field Pattern

The statistical moments of the near field are directly of use in the calculation of near-field coupling. They also provide an approximate means of evaluating the spectral power average as follows. The average spectral power is given in terms of aperture fields by

$$\begin{array}{ll}
\stackrel{\mathbf{i}}{=} & \stackrel{\mathbf{i}}{=$$

for i=x,y. Similarly the average spectral field is given by

$$\langle \overline{A}(k_x,k_y) \rangle = \iint dxdy \langle \overline{E}_A(x,y) \rangle e^{-j(k_x x + k_y y)}$$
 (30)

The covariance of the spectral power is defined by

$$C_{A*A}^{1} = \langle A_{i}^{*}(k_{x}, k_{y} | A_{i}(k_{x}, k_{y}) \rangle - \langle A_{i}^{*}(k_{x}, k_{y}) \rangle \langle A_{i}(k_{x}, k_{y}) \rangle.$$
 (31)

with i=x,y. Assuming as usual that the integrals of Equations (27) and (30) are evaluated by quadrature, and after some rearrangement this can be written as:

$$C_{A*A}^{i} = \sum_{p,q} (\sigma_{p,q}^{i})^{2} + \sum_{\substack{p \neq q' \\ q \neq q'}} C_{pp'qq'}^{i} e^{j[k_{x}(x_{p'}^{-z}_{p'}) + k_{y}(y_{q'}^{-y}_{q})]}$$
(32)

where

$$C_{pp'qq'}^{i} = \langle E_{Ai}^{*}(x_{p'}y_{q'}) E_{Ai}(x_{q}y_{q}) \rangle - \langle E_{Ai}^{*}(x_{p'},y_{q'}) \rangle \langle E_{Ai}(x_{p},y_{q}) \rangle$$
(33)

and

$$(\sigma_{p,q}^{i})^{2} = \langle E_{Ai}^{*}(x_{p}, x_{q}) E_{Ai}(x_{p}y_{q}) \rangle - \langle E_{Ai}^{*}(x_{p}, y_{q}) \rangle \langle E_{Ai}(x_{p}, y_{q}) \rangle$$
 (34)

for components i=x,y. Neglect of the cross correlation coefficients $C_{pp'qq'}$ then leads to an expression for the spectral power pattern in terms of near-field quantities that can be measured with a single probe:

$$(P(k_x,k_y)) = (A_1^*(k_x,k_y)) < A_1(k_x,k_y) > + \sum_{p,q} (\rho_{p,q}^i)^2$$
 (35)

For discussion of the validity of this approximation see [6]. It might be expected that $C_{pp',qq'}^{i}$ is small when $(\sigma_{p,q}^{i})$ is small and thus calculation of a small standard deviation suggests that Equation (35) is a valid approximation. As noted previously, the average $< A_i(k_x,k_y)>$ is a deterministic spectrum and hence the approximate average power given in Equation (35) is a deterministic pattern plus an isotropic standard deviation term. Note also that for frequency averages, the Fourier Transform of the near-field average in Equation (30) suffers from formal problems described in association with Equation (26) and becomes less

reliable as wider frequency intervals are considered. This statistical analysis is implemented in subroutine MCSUM.

The fact that the statistical average far-field is related not only to the statistical average near-field but also to the cross correlation coefficients means that a valid statistical average must be performed mode-by-mode in the far-field. That is, it is not sufficient to obtain an average near-field distribution and then, via Fourier transformation, obtain the far-field. However, it is instructive to compare the results obtained by both far-field and near-field averaging to determine the effects of the correlation coefficients.

SECTION III DESCRIPTION OF SUBROUTINES

A. Introduction

Brief descriptions of the subroutines that comprise the statistical modal computer code "PARAB" are presented here. These paragraphs reference the analytical equations implemented and are intended to show the method and technique employed without the detail of a line-by-line description. One objective is to make clear how extensions and program modifications are to be made by describing the extent to which the subroutines are interrelated. The dependence of subroutines on one another has been minimized by avoiding redefinition of common block variables and auxiliary formal parameters. The code is written in standard Fortran IV with the exception of bit-shifting in the Subroutine FFT and random number generation in FRANDOM and CRANDOM. The complete program source listing is given in Appendix I.

B. Discussion of Subroutines

1. Routine CALLER

Subroutine CALLER has two fundamental functions. The first function is the acquisition of run parameters. The second function is to establish the architecture of the program that provides for computational efficiency for differing user supplied parameters. In this role, CALLER establishes the memory allotments for the computed arrays and these variable dimension arrays are then used in the various subroutines. The arrays can then be written and read efficiently in an unformatted (binary) format allowing array space to be re-used repeatedly. The variable dimension technique is important because of core memory costs and limitations, and because it allows the varying number of modal fields in the out-of-band problem to be handled simply. The number of intervals used in evaluating the feed (FEED) and aperture (APER) Fourier integrals is given by the array size parameters (IFEED, JFEED, IAPER, JAPER). These array size parameters are the crucial determinants of the convergence of the numerical integrations and the cost (number of computations) for the specific antenna and Monte Carlo average employed.

Presently the arrays to be called with variable dimensions are all dimensioned (32) or (32,32). Thus the maximum permissible values of IFEED, JFEED, IAPER, and JAPER is 32. It is expected generally that IFEED and

JFEED can be smaller than IAPER and JAPER since the feed horn is smaller than the aperture plane (the aperture plane must be at least as large as the paraboloidal reflector). While this reduces computation considerably, no similar reduction of core requirements is available. Only the sizes of one-dimensional arrays EXOFX, EXOFY, EYOFX, EYOFY are determined everywhere by IFEED and JFEED. (Details are given in comment cards, lines 30 to 41.) Thus it is convenient to let the expected value (32) of IAPER and JAPER determine all array sizes in CALLER. If larger or smaller values of IAPER, JAPER are found desirable, the dimension statements in CALLER (lines 99 to 103) should be changed accordingly.

At card 300 of CALLER, the common blocks and array dimensions have been defined and all the run parameters have been defined and read in. Lines 300 to 311 assign values to the real array COMDAT. This array is written as a header at the top of the output files containing the Monte Carlo average field or power arrays. As noted in lines 313 to 325, the elements of this array define the x,y grid and the k_x , k_y grid obtained from it by subroutine FFT. This information is sufficient to allow a plotting program to draw scaled plots of the data. The element COMDAT (12) is intended to indicate whether x,y arrays are in the file (COMDAT (12) = 0) or k_x , k_y arrays (COMDAT (12) = 1). When file PFFDER is written, this element is reset at the write statement.

The remainder of CALLER determines the number of modes to be used in the calculation for the minimum and maximum frequencies considered and then transfers control to subroutine MCSUM.

2. SUBROUTINE COUNT

Subroutine COUNT determines what modes, within a restricted set of modes, can propagate in the waveguide of the feed system at a given frequency f. The number of such modes is then counted. The calculation of whether a mode may propagate requires only the frequency and waveguide dimensions. Specifically a mode TEmm or TMmm will propagate if

$$(f/c)^2 - (m/a_G)^2 - (n/b_G)^2 > 0$$
 (36)

where ag

ac AGUIDE = width of waveguide

b_G BGUIDE = height of wavegude.

c = speed of light.

After determining the modes that can propagate, subroutine COUNT then imposes an external restraint limiting the modes to be used. The mode is not allowed and not counted if the externally supplied array RCOEFF read from file STANCO has a complex zero in the element of the array corresponding to that mode. Modes TEmn and TMmn correspond to array elements RCOEFF (m + 1, n + 1, 1) and RCOEFF (m + 1, n + 1, 2). Allowable modes are indicated by elements of the array AMODE being +1. The arrays are dimensioned (8,8,2). Modes of higher orders than 7 can be handled by relatively minor program modifications, involving only dimension statements and limits on DO loops. This provision to exclude modes is included so that specified types of waveguide/feed devices which may generate only even or odd order modes can be modelled. For example, a coax-to-waveguide adapter which feeds the waveguide on the centerline might be expected to generate only odd-order TEmo modes. Also, future measurements of components at out-of-band frequencies may disclose characteristic mode structures.

3. SUBROUTINE MCSUM

Subroutine MCSUM determines the values taken by the random variables, either by calling subroutines which perform draws on specified distributions or by reading values produced by these subroutines, calls subroutine REFLEC to produce the deterministic near or far field for each mode, and performs the sums over modes and over the Monte Carlo ensemble to determine the near or far field and power.

The body of MCSUM consists of three physically distinct parts. The first two ts consisting of lines 43-157 and lines 164-298 perform parallel calculations and differ only in whether values of random variables are to generated (IGEN=1 branch) in the current run of the program as in lines 168-298, or read from a file presumably created by an earlier run of the program (IGEN=0 branch). This synopsis will be in terms of the IGEN=1 branch. (The IGEN=0 branch is obtained by reading from file RCOEFF at every point that the IGEN=1 branch writes on this file.)

The loops that begin at line 170 sum over the number of frequencies in the Monte Carlo ensemble. If there is no frequency averaging (IFMC=1) then the central frequency is used. The loop ends with calculation of the near-field or spectral powers as given in Equations (27) and (28). As an intermediate step the detrministic fields are calculated by the sum over allowable modes ending at line 234. (This is the inner sum

in Equation (25)). For the case of averages over coefficients, only the average near-field or spectra is calculated at line 289 as in Equation (24) with the average coefficient calculated at line 262. The more general calculation of the average field quantities given by Equation (25) is postponed to the third section of MCSUM.

The remainder of MCSUM, the third distinct part of the subroutine consisting of lines 279 to 422, completes the calculation of averages over frequency and/or modal coefficients (lines 299 to 350) and, for the case that near-field averages have been calculated (IAVGFF=0), derives the approximate far-field pattern (lines 352 to 422). Note that the frequency average in Equation (25) can be performed either with one set of coefficients $C^{i}(m,n,k)$ which is denoted as frequency only average in the program or with different sets of coefficients at each frequency, which is an average over frequency and coefficients.

The standard deviation of Equation (34) is calculated at lines 358 to 361 and the uncorrelated spectral power needed in Equation (35) is calculated at line 391. The various arrays are also written on files in this section after being normalized. Since the normalization of fields and powers are different, the arrays must be unnormalized for the calculation of standard deviations. Therefore the normalization factors are removed in lines 326 to 330 and 341 to 346.

4. SUBROUTINE CUTMODE

For the allowable modes, as cataloged by the array AMODE calculated in COUNT, the field on principle plane cuts in the feed horn aperture is calculated for each polarization. The values of the fields are stored in the one-dimensional arrays EXOFX, EXOFY, EYOFX, EYOFY corresponding to $E_{\mathbf{x}}(\mathbf{x})$, $E_{\mathbf{x}}(\mathbf{y})$, $E_{\mathbf{y}}(\mathbf{x})$, $E_{\mathbf{y}}(\mathbf{y})$. Specifically these fields are given by:

for
$$TE_{mn}$$
 for TM_{mn}

$$E_{\mathbf{x}}(\mathbf{x}') = \cos \frac{m\pi \mathbf{x}'}{a_F} , \frac{m\pi}{a_F} \cos \frac{m\pi \mathbf{x}'}{a_F}$$

$$E_{\mathbf{x}}(\mathbf{y}') = \frac{n\pi}{b_F} \sin \frac{n\pi \mathbf{y}'}{b_F} , \sin \frac{n\pi \mathbf{y}'}{b_F}$$

$$E_{\mathbf{y}}(\mathbf{x}') = \frac{m\pi}{a_F} \sin \frac{m\pi \mathbf{x}'}{a_F} , \sin \frac{m\pi \mathbf{x}'}{a_F}$$

$$E_{\mathbf{y}}(\hat{\mathbf{y}}') = \cos \frac{n\pi \mathbf{y}'}{b_F}$$

$$\frac{n\pi}{b_F} \cos \frac{n\pi \mathbf{y}'}{b_F}$$

(37)

where a_F (AFEED) and b_F (BFEED) are the x and y dimensions of the feed horn aperture. The variables $x' = x + a_{F/2}$ and $y' = y + b_{F/2}$ are the distances from a corner of the feed horn. The x, y origin is at the center of the feed horn.

Since the modal fields are separable, the x-component of the field at any point x,y in the feed horn aperture is the product $E_{\mathbf{x}}(\mathbf{x})$ $E_{\mathbf{x}}(\mathbf{y})$ and similarly for the y-components. This is true even with the inclusion of H-plane and E-plane phase tapers given by $\phi_{\mathbf{x}} = \frac{\pi f}{c} \mathbf{x}^2/h$ when the horn flares in the H-plane, and $\phi_{\mathbf{y}} = \frac{\pi f}{c} \mathbf{y}^2/h$ when the horn flares in the E-plane. The variable h(HORLEN) is the length of the horn and is supplied by the user. A special branch allows zero phase taper to be implemented by entering HORLEN = 0.0. The phase taper is proportional to the frequency and so becomes larger the further out-of-band the frequency is. The effect of the phase taper therefore is larger than in the in-band problem.

The fields on the principle plane cuts are calculated at IFEED equally spaced points for functions of x and at JFEED points for functions of y. The array sizes IFEED and JFEED are supplied by the user and are arbitrarily less than 32. The first point of each array is at the edge of the feed horn and value stored in this element is the average of the field at that wall and at the far wall. This is appropriate since these arrays will be used for numerical integration and the half-interval nearest each wall is to be accounted for.

SUBROUTINE FRANDOM

Subroutine FRANDOM returns a random value of the frequency selected from the user specified frequency distribution. The selected frequency is restricted to the interval $f_0 + \Delta f$ where $f_0(\text{FREQ})$ and $\Delta f(\text{DELFREQ})$ are the user selected nominal out-of-band frequency and the frequency spread. Uniform and Gaussian frequency distributions have been implemented and are specified by IFDIST = 1 and IFDIST = 2, respectively. The Gaussian distribution is characterized by a mean f_0 and standard deviation of $\Delta f/2$. The Gaussian distribution is modified in that elements that are more than two standard deviations from the mean are rejected and recomputed. This affects less than four percent of the sample.

Additional distributions can be implemented by the user.

6. SUBROUTINE CRANDOM

Each call of CRANDOM generates a complex modal coefficient for each allowable mode with the amplitude and phase of the coefficient selected from user specified distributions. The statistical amplitude distributions implemented are: uniform (ICDIST = 1), Gaussian (ICDIST = 2), and a 1/(m + 1)(n + 1) distribution where m and n are the orders of the TE or TM modes (ICDIST = 3). The Gaussian distribution is specified by a mean of one and standard deviation of one half, but with negative amplitudes rejected and recomputed. While the absolute amplitude is arbitrary, different standard deviations do lead to different physical results and represent a degree of freedom not implemented in the program. The mode dependent amplitude distribution of ICDIST = 3 is similar to the modal distribution excited by a coax-to-waveguide adapter and is an example of a distribution reflecting mode dependent device characteristics.

Uniform and Gaussian phase distributions are provided and correspond to IPHIRV values of 1 and 2. Since the absolute phase is irrelevant, both phase distributions are given zero phase mean. The uniform phase distribution produces an ensemble of phases distributed uniformly over the interval *PHIDEV (degrees). The standard deviation of the Gaussian distribution is PHIDEV. Other phase or amplitude distributions are easily added.

7. SUBROUTINE UNIFOR

Subroutine UNIFOR calls an external random number generator that returns a random value in the interval zero to one and redistributes this variable on the interval CENTER * SPREAD uniformly.

8. SUBROUTINE GAUSR

Subroutine GAUSR calls an external random number generator that returns a random value in the interval zero to one and redistributes this variable according to a Gaussian distribution with mean zero and standard deviation one.

9. SUBROUTINE REFLEC

Subroutine REFLEC performs the principal deterministic portions of the calculation. Specifically, the values of the direction cosines about the feed horn such that rays in these directions will be reflected by the paraboloid onto a rectangular grid in the aperture are calculated. The modification of this for far-field calculation discussed in connection with Equation (26) is implemented in lines 40 to 50. The far-field of the feed

horn for these values of KXAPER and KYAPER is calculated by 1-D Fourier integrals over the separable modal feed horn fields. Note that the calculation is a vector calculation. Provisions for feeds not at the focus can be made as suggested in lines 133 to 152.

10. SUBROUTINE FFTDOUB

Subroutine FFTDOUB is a specialized algorithm designed to transform N_X x N_y arrays of x-y data with spacings Δx , Δy into arrays in k_X, k_y space with spacings

$$\Delta k_{x}^{d} = 1/2 \pi / (N_{x} \cdot x) = 1/2 \Delta k_{x}$$

$$\Delta k_{y}^{d} = 1/2 \pi / (N_{x} \cdot y) = 1/2 \Delta k_{y}$$
(38)

while preserving the fundamental speed of the FFT and minimizing additional storage requirements. These spacings are half what the simple FFT would yield. Since the x-y array and the k_x - k_y array are the same size, the maximum k_x and k_y are half those normally obtained by the FFT. This subroutine is of use for high gain antennas where the major spectral components are near the boresight direction. It provides better resolution in the forward direction and drops the less important wide-angle components. An alternative means of calculating points more densely is a linear or polynominal interpolation. The FFTDOUB algorithm is a Fourier interpolation and determines all points with an accuracy consistent with that of the FFT.

The basic operation implemented in the algorithm is as follows

$$A(n \triangle k_{x}, m \triangle k_{y}) = FFT[E]$$

$$= \iint dxdy \ E(x,y)e^{j(n\triangle k_{x}x + m\triangle k_{y}y)} \Big|_{discrete}$$

so that

$$A(n \triangle k_x + \frac{1}{2} \triangle k_x, m \triangle k_y) = \iint dxdy \ E(x,y)e^{j1/2\Delta k_x} x e^{i(n\Delta k_x x + m\Delta k_y y)} \Big|_{discrete}$$

$$= FFT \ [E(x,y)e^{j1/2\Delta k_x} x^x]$$
(40)

Thus by multiplying the E-field array by appropriate factors and performing the FFT, the spectral components at positions offset from those produced by the direct FFT are found. By identical arguments $A(n \triangle k_x + \frac{1}{2} \triangle k_x)$, $m \triangle k_y + \frac{1}{2} \triangle k_y)$ and $A(n \triangle k_y)$, $m \triangle k_y + \frac{1}{2} \triangle k_y)$ are determined. By merging all of these with $A(n \triangle k_x)$, $m \triangle k_y)$ found directly from FFT [E], the array of spectral components with spacings $A k_x$, $A k_y$ is determined. Only the middle $A k_x$ is a subset of these points is retained. The same array spacings and numerical values of the spectral components can be obtained by the FFT of a $A k_x$ array consisting of zeroes and the original $A k_x$ array at its center. This requires more computation and storage.

11. SUBROUTINE FFT

Subroutine FFT is a realization of the well-known Fast Fourier Transform algorithm for complex two-dimensional arrays. In this specific implementation, the origin of the coordinate system and of the transformed coordinate system is at the $\rm N_{\rm X}/2+1$, $\rm N_{\rm y}/2+1$ point of the array (the array is dimensioned $(\rm N_{\rm X}, N_{\rm y})$ with N_X + N_y being integer powers of two). Also the symmetric normalization of the Fourier Transform pair is used so that the sums that form the transform and inverse transform are multiplied by $1/\sqrt{N_{\rm X}-N_{\rm y}}$.

The FFT is organized so that an array that is regularly spaced is transformed into another regularly spaced arrays. The spacings of the points of the array in x, y and in k_x , k_y are related by

$$\Delta k_{x} = \pi/(N_{x} \cdot \Delta X)$$

$$\Delta k_{y} = \pi/(N_{y} \cdot \Delta Y)$$
(41)

12. SUBROUTINE NORMIM

Subroutine NORMIM takes two variably dimensioned complex twodimensional arrays denoted by "ARRAYX(ISPEC, JSPEC)" and "ARRAYY(ISPEC, JSPEC)" and finds the element with the largest magnitude. The array that this element occurs in is noted and the location of the element in this array is recorded. Both arrays are then divided by this complex element.

The intended use of this subroutine is normalization of parallel and cross polarized field components with the preservation of relative normalization.

13. SUBROUTINE NORMXY

Subroutine NORMXY takes two variably dimensioned real two-dimensional arrays denoted by "ARRAYX(ISPEC, JSPEC)" and "ARRAYY(ISPEC, JSPEC)" and finds the element with the largest magnitude. The array that this element occurs in is noted and the location of the element in this array is recorded. Both arrays are then divided by this element.

The intended use of this subroutine is normalization of parallel and cross polarized components of the power with the preservation of relative normalization.

SECTION IV NUMERICAL SIMULATIONS

A. Introduction

The numerical algorithm described in the previous sections has been tested and results obtained for two representative antennas with a variety of frequency and modal coefficient distributions. The physical parameters of these antennas are listed in Table I. The results for these initial trials are presented as 3-D patterns of the near-field or spectral power. Parameters such as main beam pointing direction, 3 dB beam width, and average sidelobe level can be determined from these patterns. The importance of these global parameters will depend on the geometry of the problem being addressed. Thus, in different coupling problems, statistical averages of the sidelobe level over different solid angles might be crucial. More directly, the out-of-band pattern may not exhibit a distinctive main beam, thus making impractical a description in terms of beam widths and pointing directions. Thus ,it is prudent initially to examine the out-of-band pattern in detail to ascertain clearly the effects of differing distributions of the random variables and changes in the modal content. The discussion of numerical results will also emphasize use of the program and control of numerical convergence and computational cost.

B. Single Mode Patterns

The numerical code is, of course, applicable to the in-band problem. In fact, the tailoring of the code to the out-of-band problem consists principally in the choice of modal coefficients as random variables with the implication that these coefficients vary significantly for antenna ensembles of interest. It is therefore convenient to examine the numerical aspects of the deterministic calculation at the in-band frequency. For antenna 1 (see Table I) deterministic patterns are calculated at the in-band frequency of 3 GHz by selecting IRV=1 and ICSETS=1 as input parameters. A complete input list is given in Table II as the Run A column. This run uses 32 by 32 arrays to describe both the feed horn fields and the aperture fields. When the program is run with IFEED=JFEED=16 and all other parameters the same, the answer varies by less than 1%. This indicates that the integrals over the feed horn have converged for this array size. Since the feed horn is electrically small

at this frequency, this degree of convergence is not surprising. Reducing the aperture arrays also to 16 by 16 produces variations of roughly 3%. Note that the aperture plane is several wavelengths in extent. It is thus advisable to use IAPER=JAPER=32 particularly at higher frequencies. The array sizes, of course, govern the number and hence cost of computations. The run times (which vary between successive identical runs) are consistent with the total number of calculations being proportional to IFEED + JFEED and to JAPER. JAPER. This indicates that essentially all the computation is related to the arrays. The roughly linear dependence on the feed horn array dimensions is a result of the one-dimensional Fourier integrals used to construct the aperture plane fields. Similarly the number of computations is proportional to the number of points in the aperture plane as given by the product of aperture array dimensions. The far-field patterns for this in-band case are given in Figure 3 for the parallel poalrization and Figure 4 for the cross polarization. The cross polarized component arises wholly from the rotation of polarization by the reflector and is zero on the principal planes. Note that the above procedure, varying the feed and aperture array sizes in the calculation of the pattern for a single mode, is the recommended way to validate the degree of numerical convergence and to minimize computation time.

Calculations of antenna l at the out-of-band frequency of 6 GHz are presented next. Again it is instructive to examine single modes. This is accomplished by using the external file STANCO to restrict the modes used in the calculation as described in the comments of routine CALLER. Specifically, the file STANCO, a specimen of which is included at the end of the program listing in Appendix I, contains a value of the modal coefficient for each mode. If this supplied value is zero, then the mode is not used in the calcuation, see subroutine COUNT. The deterministic patterns of the TE20 mode for antenna 1 are given in Figures 5 and 6 for the parallel and cross polarized spectral power components. Figures 7 and 8 are the similar TE20 patterns obtained by a Monte Carlo frequency average over 10 frequencies selected from a Gaussian distribution on the interval 5.5 GHz to 6.5 GHz. The effects of the frequency averaging, evident by comparison of Figures 5 and 6 and Figures 7 and 8 are not dramatic. The principal effect of the frequency average is to reduce the average level of the lobes away from the forward direction, presumably this is accomplished

by changing the positions of the low sidelobes and then reducing them by the averaging. The effects of the frequency average in the forward direction are negligible. Using the same ensemble of frequencies, the averaging can be performed in the near-field and an approximate far-field pattern derived as in Section II.D. The results of this computation are shown in Figures 9 and 10. Note that the standard deviations associated with Figures 9 and 10, referenced to the peak of the parallel component, are -47 and -57 dB, respectively. The result given in Figures 9 and 10 more nearly resembles the deterministic patterns of Figures 5 and 6 than the frequency averaged patterns of Figures 7 and 8. This principally reflects the arbitrariness in the pattern derivation from near-field averages that exists for frequency averages due to the different criteria used in selecting aperture points for near-field and far-field averages described in Section II.C. For coefficient averages, the near-field derived result does not suffer this ambiguity. Thus a coefficient average produces the parallel components given in Figures 11 and 12 for a far-field average and for pattern derived from a near-field average, respectively. The standard deviation associated with Figure 12 is -37 dB. Comparison of Figures 11 and 12 indicates that the standard deviation and neglected cross correlation terms are comparable since the patterns are very similar over the 40 dB range plotted.

The computational cost of the average over 10 frequencies is roughly 10 times the cost of the deterministic calculation. This is because the calculation must start from the feed horn fields at each new frequency. The total cost of an average over 200 sets of coefficients is between three and four times that of the deterministic calcuation. The coefficient average is accomplished by reading and re-reading the modal aperture fields.

It was determined, by varying the size of the ensemble in the coefficient average, that the use of 25 Monte Carlo sets is sufficient for most purposes. For instance, the standard deviations calculated by Equation (34) change by 3 dB between sets of 25 and sets of 200 modal coefficients. For sets of 7 modal coefficients, the standard deviations differ by roughly 10 dB from the numbers obtained from larger ensembles and from other trial with 7 sets. In the multi-mode calculations, the additional sum over modes reduces the sensitivity to the number of Monte Carlo sets.

The near-field derived spectral power pattern of the parallel polarized component for the ${\rm TE}_{20}$ mode of antenna 1 operating at 6 GHz calculated by Monte Carlo average over 25 coefficients distributed as 1/(m+1)(n+1) in amplitude and Gaussian in phase with a standard deviation of 20° . Figure 12.

C. Multi-Mode Patterns

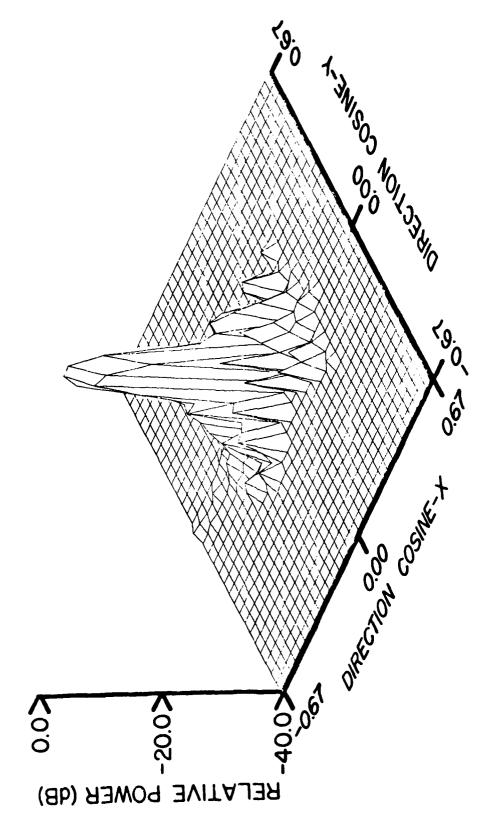

The frequency average of 10 Gaussian distributed frequencies in the interval 5.5 GHz to 6.5 GHz with allowable modes TE_{10} , TE_{11} , TE_{21} , TM_{11} produces the far-field averaged patterns of Figures 13 and 14. The modal coefficients determined from file STANCO are set to one for each mode and frequency. Note that the nominal cross polarized component is larger than the nominal parallel component.

The patterns derived from near-field averages have standard deviations of -44 dB and -41 dB and are not visibly different from Figures 13 and 14 and so are not reproduced. (The single mode calculation was more useful in indicating the effects of the frequency average and the faults of the result derived from near-field frequency averages.) The run parameters of the far-field frequency average represented by Figures 13 and 14 are given in Table II as Run B. The frequency average is expensive and does not produce dramatic results. The remaining results will be for coefficient averages only.

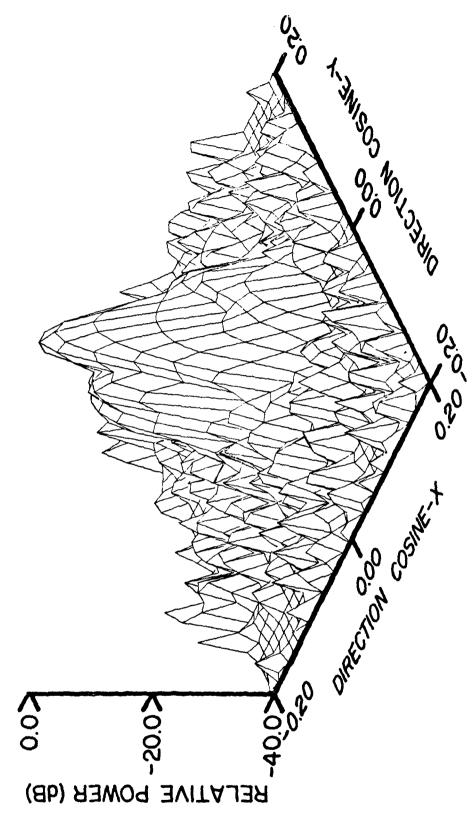

Monte Carlo averages over 25 sets of coefficients for all propagating modes of antenna 2 in Table I at a frequency of 9.6 GHz were performed. The propagating modes are TE_{10} , TE_{20} , TE_{30} , TE_{01} , TE_{11} , TE_{21} , TM_{11} , and TM21. Results are presented for a coefficient amplitude distribution proportional to 1/(m+1)(n+1) where m and n are the orders of the mode and with coefficient phases distributed uniformly over #200 and #1800. The far-field averages for the nominal parallel and cross polarized components for these cases are given by Figures 15 and 16 and Figures 17 and 18. Note that a more detailed structure occurs in the case of the smaller phase deviation. Specifically, the peaks are narrower, the nulls deeper, and sidelobes sharper for the small phase deviation as a result of greater coherence between the elements of the Monte Carlo ensemble. Since the phase of the coefficients in Figures 17 and 18 is completely random and uniformly distributed over the entire 360° cycle, it is apparent that considerable cancellation can occur. Specifically, the near-field average field of Equation (24) will approach zero for large enough samples. This tendency to cancellation in the random phase case is also evidenced by a greater than two to one ratio of the unnormalized maxima of Figures (15) and (17). For the random phase calculation, the patterns derived from near-field averages are associated with standard deviations of -1 dB and -2

The spectral power pattern of the parallel polarized component for modes TE $_{10}$, TE $_{11}$, TE $_{21}$, and TM $_{11}$ of antenna 1 calculated by Monte Carlo frequency average over 10 frequencies Gaussian distributed between 5.5 and 6.5 GHz. Figure 13.

The spectral power pattern of the parallel polarized component for antenna 2 operating at a frequency of 9.6 GHz calculated by Monte Carlo average over 25 coefficient sets distributed as 1/(m+1)(n+1)in amplitude and uniformly distributed in phase over the interval $\pm 20^{\circ}$. The modes are $\pm \epsilon_{10}$, TE $_{20}$, TE $_{30}$, TE $_{01}$, TE $_{11}$, TE $_{21}$, TM $_{11}$, and TM $_{21}$. Figure 15.

THE STATE OF THE STATE OF

The spectral power pattern of the parallel polarized component for antenna 2 operating at a frequency of 9.6 GHz calculated by Monte Carlo average over 25 coefficient sets distributed as 1/(m+1) (n+1) in amplitude and uniformly distributed in phase over the interval $\pm 180^\circ$. The modes are TE $_{10}$, TE $_{20}$, TE $_{30}$, TE $_{11}$, TE $_{11}$, and TM $_{21}$. Figure 17.

dB. Consideration of Equation (34), in light of the comments about Equation (24) above make it evident that such large deviations are to be expected. The near-field derived patterns are deterministic patterns of the antenna but have no detailed relation to far-field averaged patterns. The parallel near-field derived component is shown in Figure 19.

The near-field derived results for the limited ±20° phase variation are more interesting. These are given in Figures 20 and 21 and are to be compared to Figures 15 and 16, respectively. The associted standard deviations are -27 dB and -27 dB. The patterns are quite similar to the far-field averages down to this level (~-27 dB) except in the boresight direction. The near-field derived result predicts considerably less power in the boresight direction than actually occurs. This is evidence of a large boresight contribution from the neglected cross correlation terms.

Reducing the phase deviation to ±50 has little effect. For instance, the standard deviations of the near-field derived patterns are -27 dB and -28 dB. The conclusion is that the phase deviation of the modal coefficients is the most crucial factor to be supplied by the analysis of the feed system for any specific application.

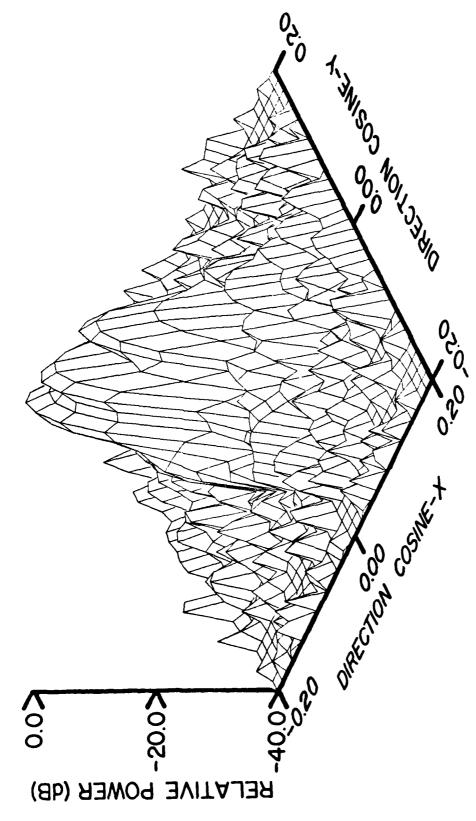

The same coefficient averaging with a phase deviation of $\pm 20^{\circ}$ has been performed with restricted mode sets. At 14 GHz only the TE₁₀ and TE₃₀ modes were used and at 16 GHz only the TE₁₀, TE₃₀, and TE₅₀ were used. The observations are qualitatively the same as for the unrestricted mode set. In particular, the near-field derived result is smaller about the boresight direction than the actual result. Patterns for these cases are not presented herein.

D. Summary

ļj

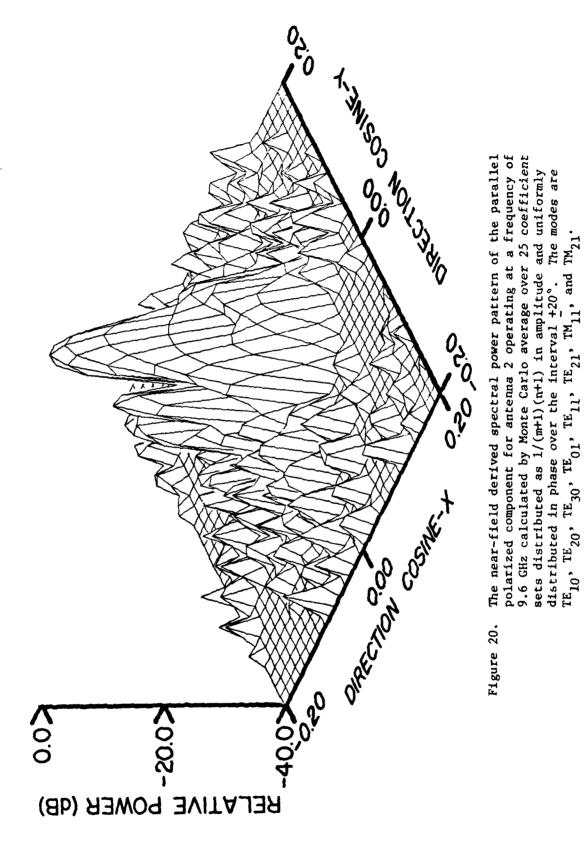

Examples of results and of the use of the program have been given. Specifically, means of validating the convergence of integrals and of the statistical factors have been demonstrated and typical values of parameters producing satisfactory results have been given.

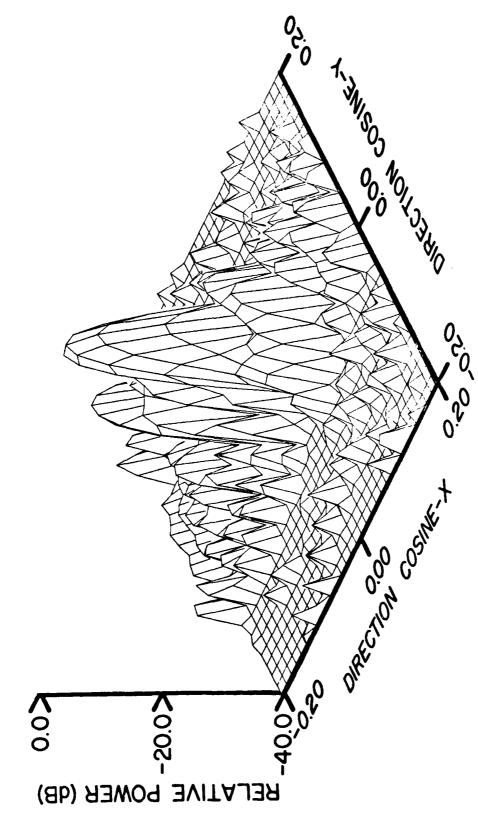

The principle observations of this preliminary study are as follows. The far-field frequency average has as its most noticeable effect the reduction of the far out sidelobes. This is most apparent for single mode calculations. The patterns derived from near-field averages are not strictly applicable in the case of frequency averaging because the same set of aperture points corresponds to different far-field directions for different frequencies.

The near-field derived spectral power pattern of the parallel polarized component for antenna 2 operating at a frequency of 9.6 GHz calculated by Monte Carlo average over 25 coefficient The modes are sets distributed as 1/(m+1)(n+1) in amplitude and uniformly distributed in phase over the interval +180°. The TE 10, TE 20, TE 30, TE 01, TE 11, TE 21, TM 11, and TM 21. Figure 19.

THE PARTY OF

The near-field derived spectral power pattern of the cross polarized component for antenna 2 operating at a frequency coefficient sets distributed as 1/(m+1)(n+1) in amplitude and uniformly distributed in phase over the interval $+20^{\circ}$. The modes are TE_{10} , TE_{20} , TE_{30} , TE_{11} , TE_{21} , TM_{11} , TM_{11} , TM_{12} , TM_{13} , TM_{13} , TM_{14} , $TM_$ of 9.6 GHz calculated by Monte Carlo average over 25 and TM₂₁. Figure 21.

Thus, for frequency averaged results, the near-field derived and far-field patterns differ by amounts greater than the standard deviation and are not expressible as the neglected cross correlation terms. For coefficient averages, the cross correlation terms are apparently comparable to the standard deviations except about the boresight direction where large cross correlations are observed. Thus, the far-field averaging, employing a Monte Carlo procedure is the presently preferred method for utilizing the out-of-band reflector antenna computer model.

The total number of computations is roughly proportional to the sum of the feed horn array dimensions and the product of the aperture plane array dimensions. If N computation cylces are required for the deterministic calculation with a single mode, then roughly M N cycles are required for M modes and N_f M N for a frequency average of an N_f element ensemble of M modes. The coefficient average is much more efficient requiring perhaps M N(1+N_C/50) computation cycles for a coefficient average over an ensemble of N_C coefficient sets for M modes.

SECTION V CONCLUSIONS AND RECOMMENDATIONS

The numerical code PARAB developed during this project provides the capability to simulate statistical out-of-band performance of paraboloidal reflector antennas under very general excitation conditions. Determination of these conditions, specifically the frequency and modal coefficient distributions, is the essential step in adapting this capability to a particular problem. The numerical simulations reported herein indicate that the far-field patterns are not particularly sensitive to frequency averaging alone. The patterns are sensitive to averages over modal coefficients at a single frequency or to both modal coefficient and frequency averaging. The greatest observed sensitivity is to the phase coherence of the modal coefficients comprising the statistical ensemble. This result indicates that the out-of-band pattern changes observed in measurements performed over frequency bands are primarily due to the phase coherence of the modes.

The code was developed to calculate statistical averages either in the near-field or far-field of the antenna. The results can thus be applied to a wide class of electromagnetic interference problems. The code also provides an approximate evaluation of the statistical far-field in terms of these statistical near-field. The simulations indicate that far-field patterns derived from the near-field averages are valid away from boresight if the computed standard deviation is small. An examination of the standard deviation thus provides a means of evaluating whether near-field measurements of antennas operating at out-of-band frequencies will yield satisfactory results.

It is recommended that other parameters, such as average sidelobe level over specified regions, beam pointing direction, and probability curves for signal strength applicable to specific problems be developed. The effects of geometrical blockage and edge diffraction can be incorporated in the code and may be of importance in many applications. The program may also be extended for offset fed reflectors. In addition, it is recommended that future modifications of the program be made to incorporate a library of statistical distributions which model specific transmission line components such as coax-to-waveguide adapters, E- and H-

plane bends, etc. This "library" would permit the modeling of specific feed/transmission systems.

Appendix I SOURCE LISTING OF PROGRAM PARAB

The calling routine and subroutines that comprise the Fortran code PARAB are listed. The listing is heavily commented and the comments complement the subroutine descriptions of Section III. An example of the input file STANCO is included at the end of the program listing. The example given contains ones as coefficients for each mode. A zero coefficient in STANCO for a specific mode prohibits use of that mode in the calculation. For a frequency only Monte Carlo average (specified by the value IRV=1), the values in STANCO will be used as the modal coefficients for all frequencies.

```
THIS PROGRAM IS DESIGNED FOR THE MONTE CARLO ANALYSIS OF OUT-OF-BAND PARABALOIDAL REFLECTOR ANTENNAS. IT IS SPECIFICALLY DESIGNED FOR FOCAL FEED, CIRCULAR PARABALOIDAL REFLECTORS WITH RECTANGULAR FEED HORNS. E-PLANE AND/OR H-PLANE FLARES ARE PERMISSABLE. OFFSET FEEDS COULD BE ACCOMMODATED WITHOUT MAJOR PROGRAM MODIFICATION. THE PRINCIPAL APPROXIMATIONS ARE THE USE

```
SUBROUTINE FFTDOUB(ARRAY, HOLDER, ISPEC, JSPEC, INVFFT)
 1
                      SUBROUTINE FFTDOUB IS A SPECIALIZED PROCRAM WHICH UTILIZES THE FFT TO PRODUCE A TRANSFORM ON A HALF-SPACED GRID -E.G.-
                 C
                 C
                                            DELKX=PI/(N*DELX)
                           FOR FFTDOUB: DELKX=1/2*PI/(N*DELX)
                      THIS CIVES IMPROVED RESOLUTION ABOUT THE BORESICHT DIRECTION FOR THE TRANSFORMED FUNCTION AT THE COST OF HALVING THE REGION OF THE TRANSFORM VARIABLE OVER WHICH THE FUNCTION IS
10
                 CCC
                       DETERMINED.
                      THE ALGORYTHYM EMPLOYED IS EQUIVALENT TO PUTTING THE INPUT ARRAY INTO A LARGER ARRAY AND ZERO-FILLING, BUT AVOIDS THE STORAGE WASTE ASSOCIATED WITH THIS.

```
SUBROUTINE FFT(SPEC, NX, NY, ISN)
                       SUBROUTINE FFT CALCULATES THE FAST FOURIER TRANSFORM OR THE INVERSE FAST FOURIER TRANSFORM OF AN INPUT TWO DIMENSIONAL, COMPLEX ARRAY AND RETURNS THE
                       RESULT IN THE SAME ARRAY
                       NX AND NY ARE THE DIMENSIONS OF THE ARRAY AND MUST
                       BE EQUAL TO 2 RAISED TO SOME POSTIVE INTEGER POWER
16
                       ISN IS THE INTEGER CONTROL VARIABLE WHICH MUST BE EITHER +1 OR -1, IF ISN=-1 THE FAST FOURIER TRANSFORM IS CALCULATED, IF ISN=+1 THE INVERSE FAST FOURIER TRANSFORM
                        IS CALCULATED
15
                       THE ORIGIN OF BOTH THE INPUT AND OUTPUT COORDINATE SYSTEMS IS LOCATED AT THE (NX/2+1, NY/2+1) POINT OF THE ARRAY
                       THE SYMMETRIC DEFINITION OF THE FOURIER TRANSFORM
                       PAIR IS USED. THE TRANSFORM AND ITS INVERSE DIFFER ONLY IN THE SIGN OF THE EXPONENTIAL WITHIN THE
20
                       INTEGRAL. IN THE DISCRETE FOURIER TRANSFORM, THIS MEANS THAT THE SUMS IN BOTH THE TRANSFORM AND INVERSE ARE MULTIPLIED BY 1/SQRT(NX*NY).
25

APPENDIX II

DETERMINISTIC SPECTRAL POWFER PATTERNS FOR SOME LOW ORDER MODES

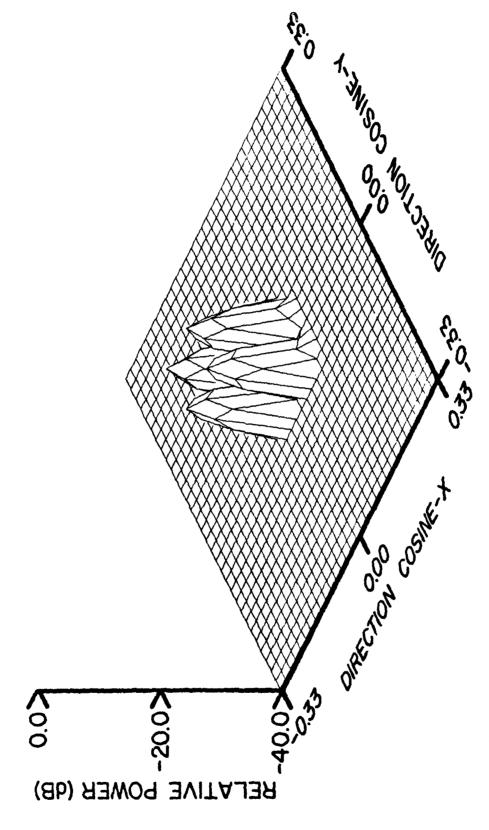

0,4/100

APPENDIX II DETERMINISTIC SPECTRAL POWER PATTERNS FOR SOME LOW ORDER MODES

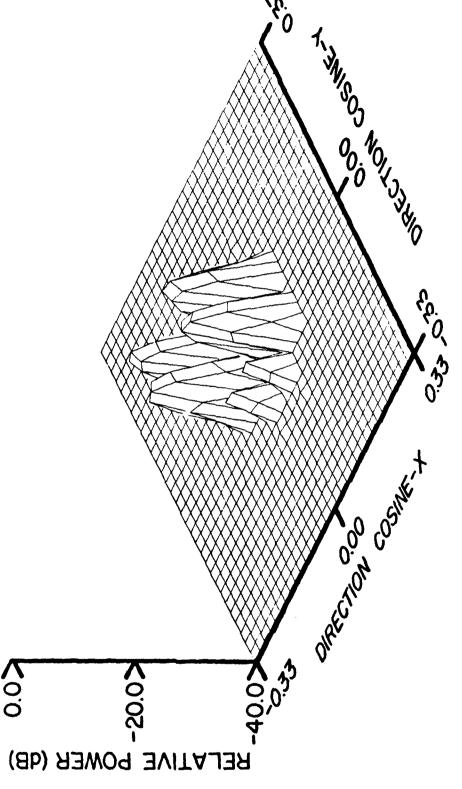

The deterministic spectral power patterns for parallel and cross polarized components of the TE_{10} , TE_{01} , TE_{11} , and TM_{11} modes of antenna 1 (see Table I) operating at 6 GHz are shown. These modes and the TE_{20} mode, equivalent patterns of which are given as figures 5 and 6, are all the propagating modes at 6 GHz. Any pattern of antenna 1 at 6 GHz is a sum of these modes with complex coefficients. The null locations and relative sizes of the parallel and cross components provide insight as to allowable modes and pattern effects in various situations. It is also interesting to compare the in-band, figures 3 and 4 and out-of-band, figures 35 and 36, patterns of the TE_{10} mode.

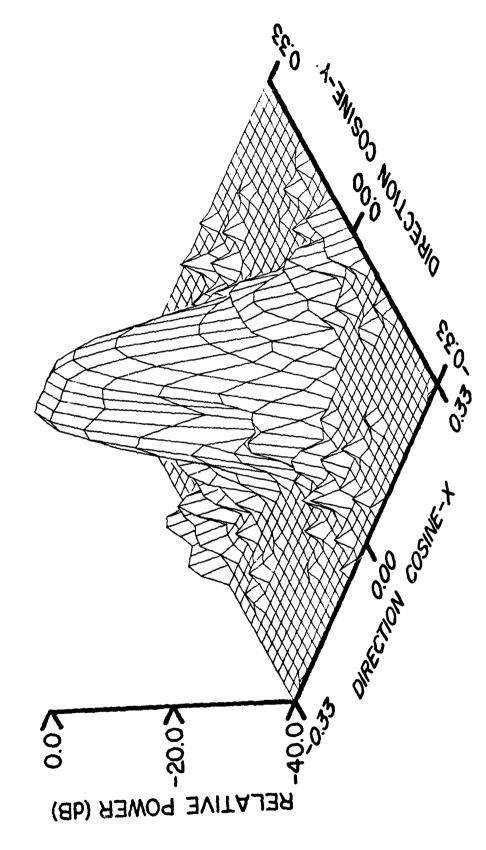

The deterministic spectral power pattern for the parallel polarized component for the TE $_{10}$ mode calculated for antenna 1 operating at a frequency of 6 $\rm GHz$. Figure 35.

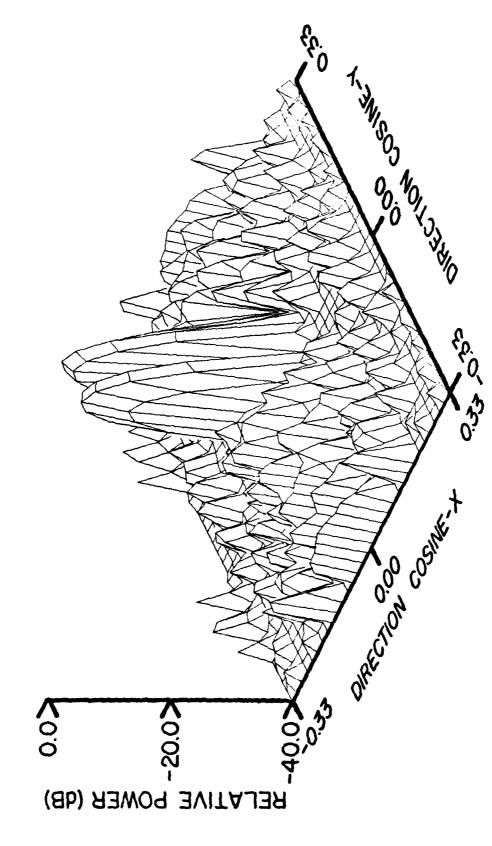

The deterministic spectral power pattern for the cross polarized component for the TE $_{\rm 10}$ mode calculated for antenna 1 operating at a frequency of 6 GHz. Figure 36.

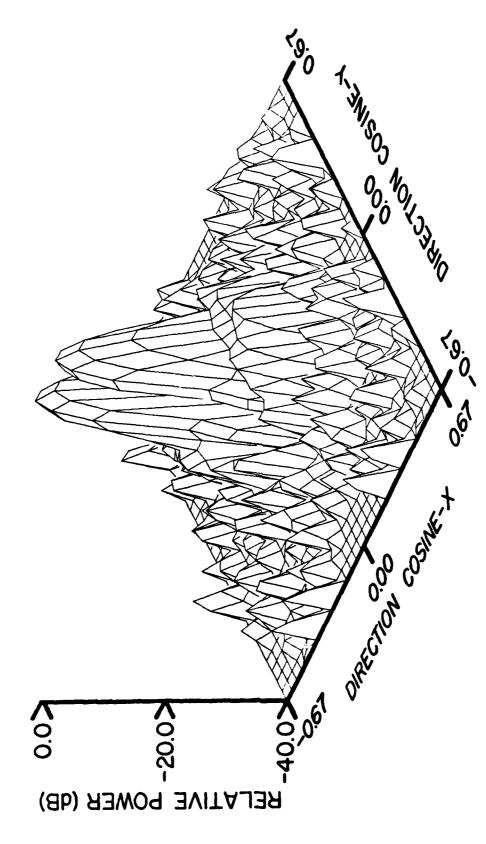

The deterministic spectral power pattern for the parallel polarized component for the TE_{01} mode calculated for antenna 1 operating at a frequency of 6 GHz. Figure 37.

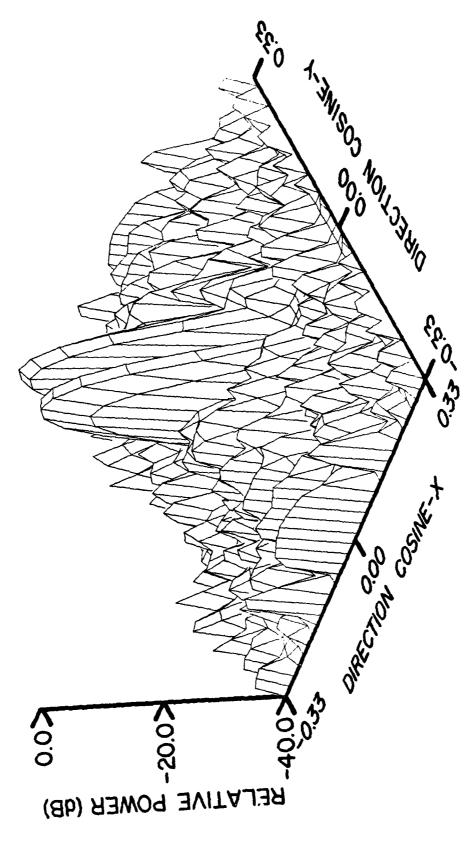

The deterministic spectral power pattern for the cross polarized component for the TE $_{01}$ mode calculated for antenna 1 operating at a frequency of 6 GHz. Figure 38.

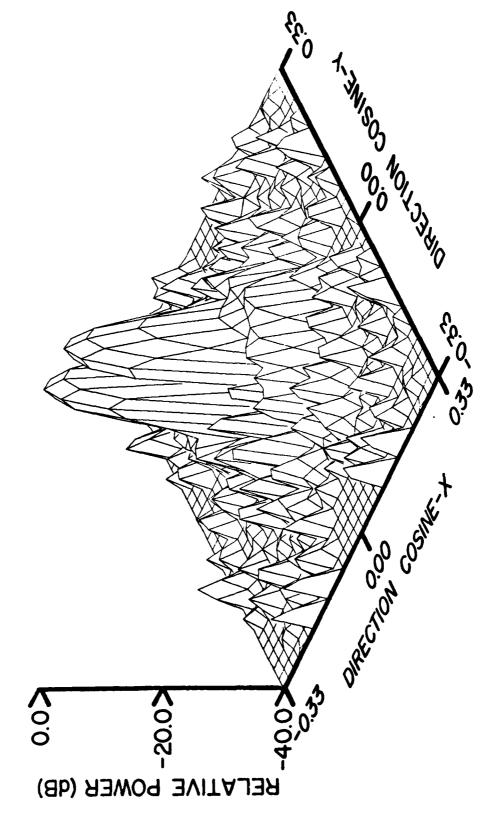

The deterministic spectral power pattern for the parallel polarized component for the TE $_{\rm II}$ mode calculated for antenna 1 operating at a frequency of 6 GHz. Figure 39.

component for the TE $_{\rm II}$ mode calculated for antenna 1 operating at a frequency of 6 GHz. The deterministic spectral power pattern for the cross polarized Figure 40.

The deterministic spectral power pattern for the parallel polarized component for the TM $_{11}^{\rm mode}$ calculated for antenna l operating at a frequency of 6 GHz. Figure 41.

component for the ${\rm TM}_{11}$ mode calculated for antenna 1 operating at a frequency of 6 GHz. The deterministic spectral power pattern for the cross polarized Figure 42.
